ABSTRACT

Lupus erythematosus panniculitis is a rare type of chronic cutaneous lupus erythematosus which is histopathologically characterized by a lobular panniculitis. We present a 43-year-old woman with an indurated painful plaque on her right flank from 3 years ago. She mentioned a previous blunt trauma to this site. Microscopic examination revealed a predominant lobular panniculitis with lymphoid follicle formation, hyaline fat necrosis, membranocystic changes and mucin deposition. She was treated with oral hydroxychloroquine with moderate improvement. An indurated subcutaneous painful plaque could be the presenting feature of lupus panniculitis and we should evaluate systemic involvement in these patients.

Key words: Lupus panniculitis; Lobular panniculitis; Lymphoid follicle

INTRODUCTION

Lupus erythematosus panniculitis (LEP) is a subtype of cutaneous lupus erythematosus which is also named lupus erythematosus profundus. Histopathologically, LEP could be characterized by epidermal changes similar to discoid lupus erythematosus (DLE) and a periseptal or lobular panniculitis [1,2].

Lymphoid follicle formation, dermal mucin deposition, hyaline fat necrosis and fibrosclerosis are other characteristic features which have been reported [2,3]. LEP usually presents by subcutaneous nodules, indurated plaques or ulcerations which involves face, proximal extremities and breast [1,3,4].

In past medical history, she had gastritis, hypothyroidism and polycystic ovary syndrome. Drug history included levothyroxine, lansoprazole and contraceptive pills.

In physical examination there was a pigmented deeply seated plaque with woody consistency on the right flank, measured 10 cm × 5 cm. Also there was periungual erythema without cuticular telangiectasia on her hands. There was no oral ulcer, cicatricial alopecia, lymphadenopathy, organomegaly, malar rash, muscle weakness, fever, weight loss and arthritis but she mentioned photosensitivity, morning stiffness, arthralgia and Raynaud’s phenomenon.

Skin biopsy was made with patient’s consent. Differential diagnoses were deep morphea, lupus panniculitis, sarcoidosis, subcutaneous T cell lymphoma (SCTCL), tuberculoid and cutaneous metastasis.

CASE PRESENTATION

We report a 43-year-old woman who developed an indurated painful pigmented plaque on her right flank. It was started 3 years ago after a blunt trauma with no improvement and gradually enlarged (Fig. 1).
in dermis, lymphoid follicles with germinal centers associated with plasmacytic and neutrophilic infiltration in deep dermis and subcutaneous fat, lobular panniculitis with hyaline fat necrosis, septal thickening and membranocystic lipodystrophy. (Figs. 2a – 2e).

Periodic Acid Schiff (PAS) staining revealed mild and focal thickening of subepidermal basement membrane. Mucin deposition was detected in colloidal iron staining. There was no acid fast bacillus in Ziehl Neelsen staining. In immunofluorescence studies only trace and focal deposits of IgG along the dermo-epidermal junction were reported (Figs. 2f – 2h).

Immunohistochemistry (IHC) studies with CD3 (pan T cell marker), CD20 (pan B cell marker), Ki67, CD68 staining were made to differentiate between LEP and subcutaneous T-cell lymphoma. The IHC confirmed mixed lymphoid aggregations of CD20 positive B lymphocytes associated with CD3 positive T lymphocytes. Ki67 staining revealed germinal centers with expected elevated proliferation rate. CD68 was positive in scattered background histiocytes and follicular dendritic cells but there was no granuloma formation. According to these findings, SCTCL was ruled out (Figs. 3a – 3d).

Blood investigations including complete blood count, urea, creatinine, liver function test, calcium, phosphorus, creatine phosphokinase, lactate dehydrogenase and complement levels were within normal limits but following lab data were elevated: Erythrocyte sedimentation rate (54 mm/1 hr.), C-reactive protein (15 mg/l; norm up to 6), antinuclear antibody (ANA: 1/160 titer with homogenous pattern), anti-double stranded DNA antibody (45 U/ml, norm up to 25) and angiotensin converting enzyme (83 U/L, norm up to 67). Urine analysis revealed leukocyturia and trace proteinuria (15 mg/dl). Urine protein was

![Figure 2: These photomicrographs show: a: Perivascular and periadnexal lymphocytic infiltration in dermis, dense lymphoid follicle aggregations in deep dermis and subcutaneous fat, lobular panniculitis and septal thickening in sub cutaneous fat. b: lymphoid follicle with germinal center associated with plasmacytic infiltration in subcutaneous fat. c: membranocystic lipodystrophy with arabesque structures and hyaline fat necrosis. d: Lymphocytic and plasmacytic perineural infiltration in deep dermis. e: Vascular impairment with neutrophilic infiltration and nuclear dust in subcutaneous tissue. f: Mucin deposition in mid dermis. g: Mild and focal thickening of basement membrane. h: Trace and focal deposits of IgG along the dermo-epidermal junction. (a: H&E, original magnification × 40; b: H&E, original magnification × 100; c: H&E, original magnification × 100, d: H&E, original magnification × 400, e: H&E, original magnification × 400, f: colloidal iron staining, original magnification × 40, g: PAS staining, original magnification × 100, h: immunofluorescence study, original magnification × 100).](image2)
Urine culture was negative. Imaging studies including chest radiography and abdominopelvic sonography were unremarkable but lesional ultrasonography revealed a hypoechoic region in subcutaneous fat.

According to clinicopathologic correlation and lab data, LEP was proposed. We treated her with oral hydroxychloroquine 400 mg daily for 12 weeks with a marked reduction in pain and induration. She was followed six monthly for any progression to systemic lupus erythematosus (SLE).

DISCUSSION

LEP is an unusual type of cutaneous lupus erythematosus which could be easily overlooked. Clinically it manifests as indurated subcutaneous painful plaques or nodules usually with normal overlying skin and mainly involves face, trunk, breast and proximal extremities [3,5], although epidermal changes including erythema, hyperpigmentation, poikiloderma, ulceration, discoid lupus erythematosus (DLE)-like features have also been reported [1,5]. It mainly affects adults aged between 20 to 60 years and women are almost twice as likely to be affected as men. Seventy percent of LEP cases have been associated with DLE but two to five percent of cases have been accompanied by SLE [6,7]. Most cases of LEP have mild and fluctuant courses but up to 15% of cases could be able to progress to SLE and 50% of them have evidences of SLE, so LEP could be a preceding feature of systemic involvement and all patients should be followed up meticulously especially in cases with positive ANA [1,3,6-8]. Arai et al. reported positive ANA in 95.2% of LEP cases [8].

Pathophysiology of LEP is not clear but hereditary C4 deficiency and trauma have been incriminated and the role of ultraviolet is questionable because LEP usually involves proximal extremities [3]. In our case, previous trauma could be a triggering factor for antigen presentation. We considered pain as a result of neural involvement which was seen in histopathologic evaluation.

Major histopathologic characteristics in LEP are as follows: Lobular lymphocytic panniculitis, lymphoid follicle formation, calcification, hyaline fat necrosis, lipomembranous changes due to vascular impairment and fibrin thrombosis. Other histopathologic characteristics include DLE-like changes in epidermis, mucin deposition (80% of cases), granuloma formation and plasmacytic infiltration. Positive lupus band and basement membrane thickening have been detected in up to 50% of cases [3,8,9]. An important differential diagnosis for LEP is SCTCL. Plasma cell infiltration, lymphoid follicle formation, mucin deposition, DLE-like epidermal changes, IHC findings and positive lupus band help to rule out SCTCL [1,10].

We treated her with hydroxychloroquine which is a disease modifier with different mechanisms and few complications [3]. For recalcitrant cases dapsone, thalidomide, cyclosporine and rituximab have been used [1].

CONCLUSION

An indurated subcutaneous painful plaque could be the presenting feature of LEP. Early diagnosis and appropriate therapy should be considered to prevent disfigurement and progression to systemic involvement.

Abbreviations

LEP: Lupus erythematosus panniculitis
SCTCL: subcutaneous T cell lymphoma
DLE: discoid lupus erythematosus
SLE: systemic lupus erythematosus
ANA: antinuclear antibody
H&E: Hematoxylin and eosin
PAS: Periodic Acid Schiff
IHC: Immunohistochemistry
