ABSTRACT

Dermatofibrosarcoma protuberans (DFSP) is a rare indolent cutaneous tumor which has been considered as a low-grade dermal and subcutaneous fibrohistiocytic neoplasm. DFSP expands slowly but recurs frequently leading to the general assumption that DFSP is a locally aggressive neoplasm. This low-grade/borderline tumor which is generally found on trunk and proximal extremities of adults has limited potential for metastasis. Clinical presentation is usually typical with a red-brown or skin coloured indurated plaque with multiple nodules or protuberances. Histopathology of DFSP is also characteristic which demonstrates storiform pattern of uniform spindle cells infiltrating deep into the subcutaneous fat tissue constituting honeycomb appearance. Here, we report a case of DFSP in a 50-year-old woman who presents with a twenty year history of slowly growing mass on her left femoral area.

Key words: Dermatofibrosarcoma protuberans; Fibrohistiocytic; Spindle-shaped

INTRODUCTION

Dermatofibrosarcoma protuberans (DFSP) is a rare low-grade soft tissue sarcoma, which usually tends to be localized though frequently exhibits signs of recurrence. Seldomly metastasizing, its locally aggressive behavior has been attributed to its tendency to multiple recurrences. Although it may arise anywhere on the body, typical site of involvement is the trunk and proximal extremities. DFSP is also an exceptional dermatological disease in that it is associated with a genetic translocation involving chromosomes 11 and 22 \([t(17;22) (q22;q13)]\) [1-5].

CASE REPORT

A 50-year-old woman was admitted to our outpatient clinic with a twenty year history of slowly growing mass on her left femoral area. Her past and family history were unremarkable. Upon dermatological examination we observed a peripherally erythematous, centrally violaceous indurated plaque with multiple nodules or protuberances on her left femoral area (Fig. 1). Histopathological examination of lesional skin biopsy demonstrated storiform pattern of uniform spindle cells infiltrating deep into the subcutaneous fat tissue constituting honeycomb appearance. Here, we report a case of DFSP in a 50-year-old woman who presents with a twenty year history of slowly growing mass on her left femoral area.

Figure 1: Peripherally erythematous, centrally violaceous indurated plaque with multiple nodules or protuberances on left femoral area.
subcutaneous fat tissue constituting honeycomb appearance (Figs. 2 and 3). Immunohistochemically tumor cells stained positively for CD34, negatively for CD68 and 5% positively for Ki67 (Fig. 3). Based on history, clinical and histopathological findings, we made a diagnosis of DFSP and the patient was referred to general surgery and medical oncology departments for the complete excision of the tumor and follow-up of the patient.

**DISCUSSION**

Dermatofibrosarcoma protuberans (DFSP) is a rare monoclonal mesenchymal sarcoma. It differs from most of the soft tissue tumors because of the fact that it is indeed slowly progressive, locally aggressive tumor and has a high rate of recurrence rates after surgical treatment. DFSP is a rare tumor, its exact incidence is not known [1-5]. Recently it has been reported that the overall incidence of DFSP in United States is 4.1 per million person-years [6].

We present this case because of the rare reported cases of DFSP in the literature. Our patient manifested typical features of DFSP, in that her history, clinical and histopathological findings were all consisted with the characteristics of DFSP. It is known that DFSP is generally located on trunk, however lower extremities are the second most common localization for DFSP [3]. Moreover, proximal regions of the limbs are more favored [4] as in our case. DFSP usually starts with one or more small, firm, flesh-colored or pink-red dermal nodules. Over a period of time, these nodules coalesce and the tumor turn into a indurated, hard plaque with multiple nodules or protuberances. A rapid growth phase has been described, which is the time that the tumor enters an accelerated expansion period. As the tumor enlarges, a dusky-reddish blue discoloration surrounding the lesion appears. Most of the time initially painless lesion turn out to be a painful tumor. Moreover, ulceration along with discharge have been described for DFSP [1-4].

The lesion of our case also manifests typical histopathological features of DFSP. It is known that DFSP has a distinctive histologic appearance. In DFSP, the dermis and subcutaneous tissue are replaced by bundles of uniform, spindle-shaped cells. Tumor cells infiltrate and merge into the deeper dermis forming bands, in which this histopathological entity is called as storiform pattern. Immunohistochemical studies can be helpful in making the diagnosis of DFSP. In our case, immunohistochemically tumor cells stained positively for CD34, negatively for CD68 and 5% positively for Ki67, which support the diagnosis of DFSP.
