ABSTRACT
Carcinoma en cuirasse is a rare and unique form of cutaneous metastases, which surrounds the trunk in a firm and leathery fibrotic fashion, like an armor. We report a case of carcinoma en cuirasse in a 53-years-old female patient who was admitted to Dermatology outpatient clinic with pruritic, red, firm papules and plaques on the left breast and arm, extending to upper abdomen and medial part of right breast. At time of admission the patient did not have a history of an internal malignancy. Histopathological diagnosis of the incisional biopsy material from the plaque lesion was consistent with invasive ductal carcinoma. Imaging studies showed axillary, paraaortic, aortocaval lymph node involvement, pleural effusion, lung and liver metastases. The patient was referred to Medical Oncology Department and was treated with cyclophosphamide and adriamycin chemotherapy. This case of carcinoma en cuirasse preceding the diagnosis of metastatic breast carcinoma and leading to diagnosis of malignancy is rare and important. Prognosis depends on the type of primary tumor and it’s biological behavior, predictably, poor prognosis is expected in this case of metastatic invasive ductal carcinoma.

Key words: Cutaneous metastases; Carcinoma en cuirasse; Breast carcinoma

INTRODUCTION
Cutaneous metastases of internal malignities, constitute 2% of all skin tumors and is important in detecting undiagnosed malignancies and relapses of inadequately treated malignancies [1]. Carcinoma en cuirasse is a rare and unique form of cutaneous metastases, in which the cutaneous metastases cause lymphatic blockage and eventual thickening of chest wall skin, dermal and subcutaneous tissue fibrosis, resulting in armor-like wrapping of the trunk [2]. It generally occurs months to years after the diagnosis of primary cancer. However, rarely it may be the primary symptom of cancer [3].

CASE REPORT
A 53–years-old female patient was admitted to Dermatology outpatient clinic with an erythematous rash on trunk and left breast. Patient’s history revealed that she had suffered from hardening and shrinking of the left breast for 2 years and it was accompanied by a pruritic rash on trunk and edema in the left arm for the last 3 months. She didn’t have any concomitant systemic diseases or use of any drugs.

Dermatological examination revealed distortion of the left areola, contraction and shrinking of the left breast, edema of the left arm and forearm. Dark red and purple colored, infiltrated, semi-firm, non-fading plaque and papules causing peau d’orange appearance was noticed on an area of approximately 50x35 cm on the left breast extending to the medial aspect of right breast, neck and abdomen (Figs. 1 and 2).

Routine blood tests, tumor markers, breast ultrasonography and mammography were performed. Overall report was BI-RADS-5, recommending tissue sampling from both breasts.

A punch biopsy with the prediagnosis of carcinoma en cuirasse was performed from the lesions on the trunk. It was reported as carcinoma metastasis, tumor cells immunostained with pan CK. Approximately 20% stained with Estrogen Receptor (ER), 10% stained with Progesterone Receptor (PR). CerbB2 score was zero. The samples showed no staining with Mammoglobeine and GCDFP15. These findings were consistent with breast cancer metastasis (Figs. 3-7). Incisional biopsy material from both breasts were consistent with invasive ductal carcinoma.

Bilateral enlarged axillary lymph nodes, pleural effusion and adjacent collapsed lung areas were detected in thorax and abdominal computed tomography. Multiple nodules were present in bilateral lungs. Multiple mass lesions showing contrast retention compatible with metastases were visualised in liver. Paraaortic and aortocaval lymph nodes were present.

Patient was referred to Medical Oncology Department and chemotherapy with the diagnosis of metastatic invasive ductal carcinoma was initiated.

**DISCUSSION**

Cutaneous metastases of internal malignities are relatively rare encountered conditions and of diagnostic importance for undiagnosed malignancies [3]. In female patients, most frequently breast cancer (69%), colon cancer (6%), melanoma (5%) and cervix cancers (2%) were accused of this condition [4].

Cutaneous breast cancer metastases can be seen in different morphological patterns such as papulonodular lesions, erysipeloid or sclerodermoid infiltrations [5]. Carcinoma en cuirasse is a special fibrotic form of cutaneous metastases, spreading rapidly and wrapping the trunk like a leather armor [6]. Lymphatic drainage

is disturbed, causing thickening of chest wall skin and edema, eventually resulting in fibrosis of the dermis and subcutaneous tissue [2]. This situation causes lymphedema, pitting of the skin and peau d’orange appearance [4,5]. Duration from cancer diagnosis to cutaneous metastasis may differ, however, generally it’s seen in 3 years following the diagnosis [5]. Rarely, in some patients cutaneous metastases may be seen as the first and/or only symptom of the malignancies [3].

CONCLUSION

This patient is worth presenting due to carcinoma en cuirasse along with breast distortion and areola retraction being the preceding symptom of breast cancer. In this case, recognizing the cutaneous metastasis was important for initiation of the treatment and preventing further metastasis.
