A 4-month-old infant was referred from surgery clinic for evaluation of *perianal warts* noticed recently by her mother. Her medical history was unremarkable and there was no suggestion of constipation, diarrhea, sexual abuse or maternal anogenital warts. Examination showed a solitary, small, fleshy, smooth surfaced, painless protrusion in the midline at superior aspect of anal verge (Fig. 1). No bleeding, excoriations, anal fissure, hemorrhoids or rectal prolapse was noted. With a diagnosis of infantile perianal pyramidal protrusion the parents were counseled about its benign nature.

Infantile perianal (perineal) pyramidal protrusion (IPPP), a relatively newly described entity, is reported primarily in female infants. Its exact pathogenesis remains unknown but is considered as (i) embryologic remnant of urogenital septum or a congenital anatomical weakness of median raphe, (ii) functional or acquired secondary to mechanical irritation from wiping, constipation/diarrhea, or fistulas/anal fissures, and (iii) lichen sclerosus et atrophicus (LSA)-associated that results from post inflammatory rearrangement of fibrous tissue [1,2]. Resolution is spontaneous especially in functional variety once the primary trigger is removed [3,4]. Topical corticosteroid may help early resolution of LSA-associated IPPP [5]. The histologic features of PPP are not defined but will exclude other simulators [4]. Nevertheless, it is imperative to differentiate the condition from simulating lesions affecting perineum/perianum such as hemorrhoids, prianal warts, condyloma, molluscum contagiosum, sentinel tag, granulomatous lesions of Crohn's disease, perineal midline malformation, rectal prolapse,

infantile hemangioma and most importantly from signs of sexual abuse to avoid unnecessary treatment and parental anxiety.
