INTRODUCTION

Treatment failure and symptomatic relapse are major concerns in New World cutaneous leishmaniasis. Such complications are seen frequently in Leishmania (L.) guyanensis infections, in which patients respond variously to first-line treatment and are at higher risk to develop chronic cutaneous leishmaniasis [1].

Leishmaniasis due to L. guyanensis has been reported from Argentina [2], Brazil [3], Colombia [4], Ecuador [5], and Peru [6].

The Surveillance of Imported Infections in Germany (SIMPID) Surveillance Network reported 42 cases of leishmaniasis in Germany during the years 2001-2004. Most of them were cutaneous diseases acquired in the Mediterranean countries [7]. Harms et al. (2011) analyzed 23 cases of New World leishmaniasis in returnees from Central or South America to Germany. In all cases L. braziliensis had been detected by polymerase chain reaction (PCR) [8].

CASE REPORT

A 19-year-old German Caucasian women returned from a 12-months stay to Ecuador where she developed ulcero-nodular lesions on the nose and arms. New World leishmaniasis was diagnosed. An intralosal treatment with glucantime once a week was initiated in Ecuador. The lesions disappeared within two months. Once months later, nodular lesions occurred on the left cheek. She also reported diarrhea and temporary muscle pain during her stay in Ecuador.

After return from Ecuador 7 months later, she presented to the clinic for further diagnostics with five deep nodular lesions on the left cheek (Fig. 1). At that timepoint, she had no fever, arthralgia or arthritis, no diarrhea. She suffered from mild fatigue.

Routine laboratory investigations were unremarkable except for revealed increased counts of eosinophils in peripheral blood – 80 Gpt/L (normal range: 0-40). Antibodies to leishmania were negative but antibodies

Key words: Travel medicine; Leishmaniasis; Trichinellosis; South America; Leishmania guyanense.
against *Trichinella* were positive. A deep skin biopsy was taken for PCR to leishmania species. PCR was positive for *L. guyanensis*.

Diagnostic ultrasound demonstrated normal cervical, slightly enlarged axillary and inguinal lymph nodes, and a mild hepatosplenomegaly. Chest-X-ray was unremarkable.

The diagnoses cutaneous leishmaniasis of the New World and trichinosis were confirmed, although hepatosplenomegaly in conjunction with fever is a symptom of visceral leishmaniasis. However, the patient had no fever, leuko- or lymphopenia, anemia or thrombocytopenia. No circulating antibodies could be detected, and her general health status was good.

We started with topical treatment of leishmaniasis after confirmation of *Leishmania spp. with paromycin* ointment, but it remained unsuccessful. After species identification, we recommended miltefostin 2.5 mg/kg body weight for 28 days.

In addition, albendazole 400 mg twice daily for 10 days was suggested for trichinellosis treatment.

**DISCUSSION**

In Germany, most cases of imported leishmaniasis belong to the cutaneous and mucocutaneous Old World leishmaniasis, while New World tegumental and visceral types are less common [7-10]. The Institute for Tropical Medicine, Berlin, registered in 2015 16 cases of imported leishmaniasis in Germany including two New World leishmaniasis infections from Brazil and Peru [11].

Here we report a case of deep cutaneous *L. guyanensis* infection relapsing after glucantime in a German returnee from Ecuador. The treatment failures and relapses with this subtype is a challenge.

*L. guyanensis* shows a limited response to antimony, since they are capable to detoxify peroxides by trypanothione. Ornithine decarboxylase (ODC) and γ-glutamylcysteine synthetase (GSH1) produce molecules that are direct precursors of trypanothione. Parasites with ODC- or GSH1-overexpression presented an increase of two and four-fold in antimony (III)-resistance index, compared with the wild-type line [12]. Another mechanism involved in antimony resistance are point mutations in the gene encoding aquaglyceroporin 1 [13].

Animal studies revealed that leishmania RNA virus 1 (LRV1), nested within *L. guyanensis* parasites, is able to exacerbate experimental murine leishmaniasis. LRV1 is recognized by the host Toll-like receptor 3 (TLR3) [14]. The virus induces strong interferon type I immune responses that diminish the level of interferon-γ production and release necessary to control leishmania infection [15].

The prevalence of LRV1 in human *L. guyanensis* infection and its relationship to treatment failure and inflammation has been investigated among 75 patients with a diagnosis of primary localized New World cutaneous leishmaniasis. The prevalence of LRV1-positive *L. guyanensis* infection was 58%. All patients infected with LRV1-negative *L. guyanensis* responded to a single or double dose of pentamidine. In contrast, 12 of 44 LRV1-positive patients (27%) presented with persistent infection and symptomatic relapse that required extended therapy and the use of second-line drugs. LRV1 presence was also associated with a significant increase in levels of intralesional inflammation. The LRV1 status in *L. guyanensis* infection is predictive of first-line treatment failure and symptomatic relapse [16]. However, we were not able to analyze our sample for LVR1 presence.

Our patient also suffered from mild trichinellosis. *Trichinella spiralis* and *T. pseudospiralis* occur worldwide. The first one is found in wild and domestic pigs and wild carnivores, the second one infects both mammals and birds. The most important source
of human infection worldwide is the domestic pig. Infection of humans occurs with the ingestion of *Trichinella* larvae that are encysted in muscle tissue and is strongly associated with the consumption of raw or undercooked meat. Diagnostics include clinical symptoms, laboratory findings (eosinophilia, elevated muscle enzymes, and serology), and epidemiological investigations. Treatment options include albendazole or mebendazole monotherapy in case of mild or abortive disease [17].

Porcine trichinellosis in Ecuador is more common in traditional setting in villages compared to farms [18]. In 2015, only 8 cases of imported trichinellosis had been registered by the Robert-Koch-Institute (RKI) in Germany, all of European origin [11].
