Sir,

Acute generalized exanthematous pustulosis (AGEP) is an uncommon disease which is usually caused by systemic medication, and its incidence is reported to be 0.35–5 per million per year [1,2]. It is especially rare for AGEP to develop on childhood. We herein describe a pediatric case of AGEP induced by ampicillin.

A 13-year-old boy was hospitalized to the Plastic Surgery Department in our hospital for surgical treatment of scar contracture after extensive burns. He was referred to our department, complaining of high fever and skin rash. In the perioperative period, he was administered ampicillin, cefaclor, non-steroidal anti-inflammatory drugs, acetaminophen, and rabeprazole sodium. Three days after from surgery, itchy erythema appeared to his back. As a result of having been given ampicillin again due to fever, the skin rash spread to a whole body rapidly. Physical examination revealed erythroderma with a number of pinpoint pustules (Figs. 1a and b). Symptoms such as hyperemia were not seen in the mucous membrane, and Nikolsky sign was negative. Laboratory data showed elevated white blood cell count (17600/μl, with 81% neutrophils), and C-reactive protein (6.36 mg/dl). Although a little staphylococci were detected in pustule, no bacteria were detected in the blood. A skin biopsy showed pustules in the epidermis with spongiform pustules, and perivascular inflammatory cell infiltration, mainly composed of lymphocytes and eosinophils, in the upper dermis (Fig. 2). After discontinuation of ampicillin and initiation of oral prednisolone (25 mg/day), the erythema and fever quickly disappeared. Patch test showed positive reaction to 10% and 20% ampicillin and negative reaction to all the other drugs used in the perioperative period.

To date, only six English literature cases of childhood AGEP have been reported. The age of patients were...
17 months [3], 4-year-old, 7-year-old, 11-year-old, 12-year-old [4], 13-year-old [5], and 14-year-old (our case). It was assumed that the skin rash was caused by amoxicillin [3], contrast agent, paracetamol, cetirizine, ketoconazole [4], and amoxicillin-clavulanic acid [5]. One case was relieved by just ceasing the application of the suspected drug [3], and other cases were needed another antihistaminic drug, corticosteroid ointment, antihistaminic drug [5], and intravenous corticosteroid [4,5]. In our case, the patient showed erythroderma, and we needed oral prednisolone. To date, there are no reports of such the serious case of childhood AGEP.

The main differentiation diagnosis is that of generalized pustular psoriasis (GPP). It is often difficult to distinguish both diseases by eruption and histopathology. It is necessary to pay attention to recurrence in long-term clinical progress to distinguish between both diseases, as AGEP only rarely recurs, but GPP recurs many times. In pediatric cases, the differentiation from Kawasaki disease is also necessary, because Kawasaki disease rarely presents with skin rash similar to AGEP, which manifests as an erythematous pustular eruption. Although rare, we should bear in mind that AGEP can occur even in children.
