Abstract
Introduction: Allergic drug reactions represent common clinical challenges. Selected allergic drug reactions present with blisters.

Case report: A 73 year old female was prescribed levofloxacin injection and trimethoprim/sulfamethoxazole for a urinary tract infection. Subsequently, the patient developed blisters on both of her hands and feet, associated with clinical pruritus. Clinically, bullae were observed on both of her palms and soles, associated with erythema.

Methods: Biopsies for hematoxylin and eosin (H&E) examination, as well as for direct immunofluorescence (DIF) were performed.

Results: Focal areas of the epidermis displayed diffuse, mild spongiosis. An acute inflammatory process extended into hair follicular units, with focal rupture of these structures. Focal subepidermal vesiculations were also noted in the areas of follicular unit rupture. DIF examination demonstrated faint linear deposits of anti-human fibrinogen at the basement membrane zone of the skin, as well as around several hair shafts. A similar fibrinogen deposition pattern also present around the upper dermal blood vessels.

Conclusions: In our practice experience, the most common cause of blistering diseases are allergic drug reactions, in contradistinction to primary autoimmune blistering disorders. Clinical physicians, pathologists and immunodermatologists should be aware that allergic drug reactions can mimic primary autoimmune blistering disorders, both clinically and in selected immunologic aspects.

Key words: cutaneous allergic drug reaction; direct immunofluorescence; biomarkers; hair follicle; trimethoprim/sulfamethoxazole; levofloxacin

Abbreviations and acronyms: Immunohistochemistry (IHC), hematoxylin and eosin (H&E), direct immunofluorescence (DIF), basement membrane zone (BMZ).

Introduction
Drug-induced allergic reactions are characterized by a spectrum of clinical and histologic patterns that include perivascular dermatitis, vesiculobullous lesions, pustular eruptions, sclerodermoid reactions, vasculitis, folliculitis/ pilar folliculitis and panniculitis [1-12]. While a single drug may elicit a range of reaction patterns, no reaction pattern is specific for a particular drug. Although the temporal link between initiation of drug therapy and the onset of the drug rash is critical to the diagnosis, drug reactions may also occur during the course of chronic drug administration [1,12].

Case report
A 73 year old female was prescribed levofloxacin injection and trimethoprim/sulfamethoxazole for a tract urinary infection. Subsequently, the patient consulted a dermatologist for development of blisters on both of her hands and feet with pruritus. Clinically, small bullae on erythematous base were seen on both of her palms and soles. Skin biopsies for hematoxylin and eosin (H&E) examination, and for direct immunofluorescence were taken in 10% formalin and in Michel’s media, respectively. Following the biopsies, the patient’s cutaneous lesions improved over a period of weeks following discontinuation of her trimethoprim/sulfamethoxazole and initiation of oral prednisone.

Methods

Direct immunofluorescence (DIF)

In brief, skin cryosections were prepared, and incubated with multiple fluorochromes as previously reported [3-8]. We utilized normal skin as a negative control, obtained from patients going under esthetic plastic surgery. To test the local immune response in lesional skin, we used antibodies to immunoglobulins A, G, M, and E, as well as Complement C3 and fibrinogen in DIF testing (all FITC conjugated, and all from Dako, Carpinteria, California). We also utilized monoclonal anti-collagen IV from Sigma (Saint Louis, Missouri, USA). We further utilized Texas red as a secondary DIF chromogen to further characterize the immune response within hair follicles.

Results

Examination of the H&E tissue sections demonstrated an acute inflammatory process. Focal areas of the epidermis displayed diffuse, mild spongiosis. The dermis displayed congested blood vessels. An acute inflammatory process extended into hair follicular units, with focal rupture of these structures. Focal subepidermal vesiculations were also noted in the areas of follicular unit rupture. A superficial, moderately florid, mixed perivascular inflammatory infiltrate was present within the dermis, featuring lymphocytes, histiocytes, neutrophils and eosinophils. No vasculitis was appreciated. Focally, necrotic epidermal keratinocytes were observed (Fig. 1). Direct immunofluorescence (DIF) studies were performed, and displayed the following results: IgG (-); IgA (-); IgM (-); IgD (-); IgE (-); complement/C1q (-); complement/C3 (+), accentuated around the upper dermal blood vessels; and collagen IV (+++) around hair follicles, sweat glands and along the basement membrane zone (BMZ). Fibrinogen (+++) was noted in a faint linear pattern at the BMZ and around dermal superficial blood vessels (Fig. 1).

Discussion

The diagnosis of an allergic drug reaction is based on a detailed clinical history, and a temporal correlation between initiation of medication therapy and onset of the rash [1-3]. Histopathology aids in the diagnosis, and immunofluorescence characterizes the nature of immune deposits. In a recent study, the most common manifestations of a cutaneous drug eruption were a maculopapular rash; other possible clinical manifestations included purpura, aeneciform lesions, TEN/Stevens Johnson syndrome, erythema multiforme, exfoliative dermatitis and other blistering reactions [11]. Associated drugs included nonsteroidal antiinflammatory drugs, antipsychotics, antibiotics, antileprotics/antitubercular drugs, steroids, antimitotics and cardiac and renal specialty drugs. Histopathological features were compatible with the clinical lesions in most of the cases. The most common immunoreactants in direct immunofluorescence were complement/C3 and fibrinogen, primarily noted around dermal blood vessels and at the BMZ [11]. Clues to the drug-induced nature of our cutaneous eruption include the presence of overlapping, incongruent histologic reaction patterns, the clinical features, and immunologic features observed in the DIF. While eosinophils represent an important histologic hallmark of an allergic drug reaction, they may also be conspicuous in skin rashes without a drug association. Furthermore, eosinophils may be histologically sparse or absent in some allergic drug reactions. Thus, increased awareness of the broad spectrum of cutaneous pathology and direct immunofluorescence patterns elicited by an increasing range of therapeutic agents is critical to the proper diagnosis of these disorders. Significantly, in our case, the DIF results do not represent a classic pattern observed in any primary autoimmune blistering disease.
